

**convex risk**

# Equilibrium Risk Pools in a Regulated Market with Costly Capital

Stephen J. Mildenhall

October 27, 2020

Why is Florida  
homeowners written in  
monoline companies?

## Context and Literature

- Capital allocation and multiline pricing: perfect markets with frictional costs of holding capital and ex post **equal priority** default rule
  - Phillips, Cummins, Allen (JRI 1998)
  - Myers, Read (JRI 2001)
  - Sherris (JRI 2006)
  - Ibragimov, Jaffee, Walden (JRI 2010)
  - Cummins (RMIR 2000): frictions caused by tax, regulation and agency problems
- We assume the opposite: **imperfect market** but **no frictional costs of capital**
  - Risk cost of capital is not a friction
  - Rationale: catastrophe bond pricing

## Context and Literature

- Charge for risk using a non-additive **distortion (spectral) risk measure (DRM)**
  - Wang (ASTIN 1996), Wang, Young, Panjer (IME 1997)
- Possible rationale: **ambiguity averse** investors charge for shape of risk
  - Klibanoff, Marinacci & Mukerji (Econometrica 2005)
- DRMs are non-additive, but they are still **consistent with general equilibrium and no arbitrage** prices
  - De Waegenaere, Kast, and Lapied (IME 2003), Chateauneuf, Kast, Lapied (Math Fin 1996)

## Context and Literature

- Diversification traps: Ibragimov, Walden (JB&F 2007) applies with very thick tails
- Ibragimov, Jaffee, Walden (Rev Fin 2018)
  - Perfect market with frictional cost of holding capital
  - One-sided protection rather than risk pooling
  - ***“Basic structure questions in a risk market with one-sided protection remain unanswered.”***
  - Show monoline solutions more likely when risks asymmetric or correlated
  - We show qualitatively similar results with entirely different assumption
- Presentation partly based on joint work with John Major (arxiv 2020)

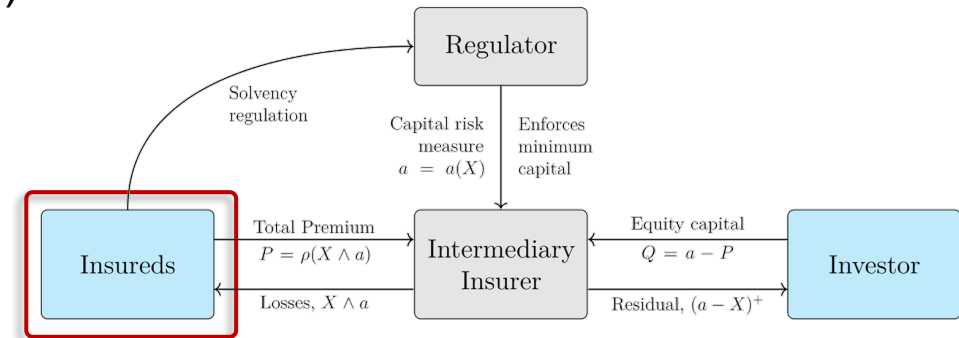

# Four actors and market interactions

- Standard simplifying assumptions: no expenses, no investment income
- One-period model
- $X \wedge a = \min(X, a)$

## Insured buying behavior

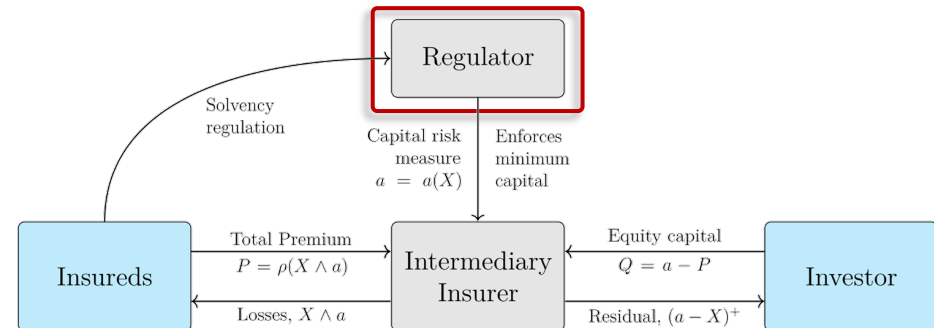

- **Face mandatory / quasi-mandatory insurance requirement**
  - 60% of premium (Aon Benfield, 2015)

- **Mandate is for third-party protection**
  - Insureds do not care about insurer solvency provided policy satisfies mandatory requirement, e.g., guarantee funds or judgment proof
- Insureds are pure price buyers, do not see quality differences

## Regulator

- **Solvency regulation necessary to ensure mandatory insurance effective, Cummins (JoF 1988)**

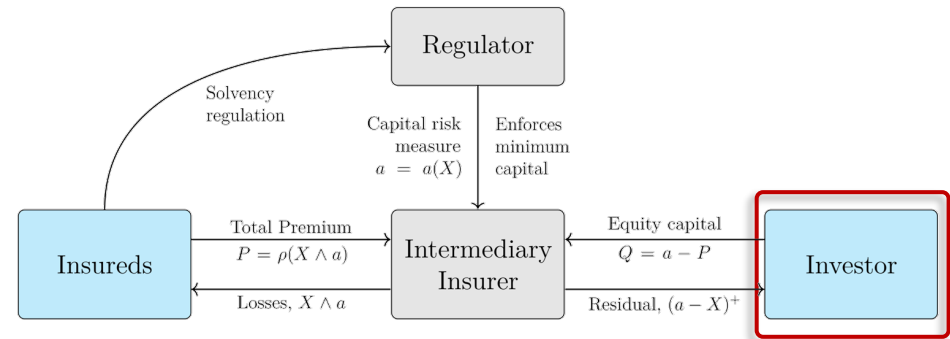

Incorporeal: regulator is a formula

- Regulatory capital standard risk functional  $a = a(X) = a(\text{total risk})$ 
  - **Value at Risk (VaR)** or tail value at risk
- No other regulation beyond capital standard

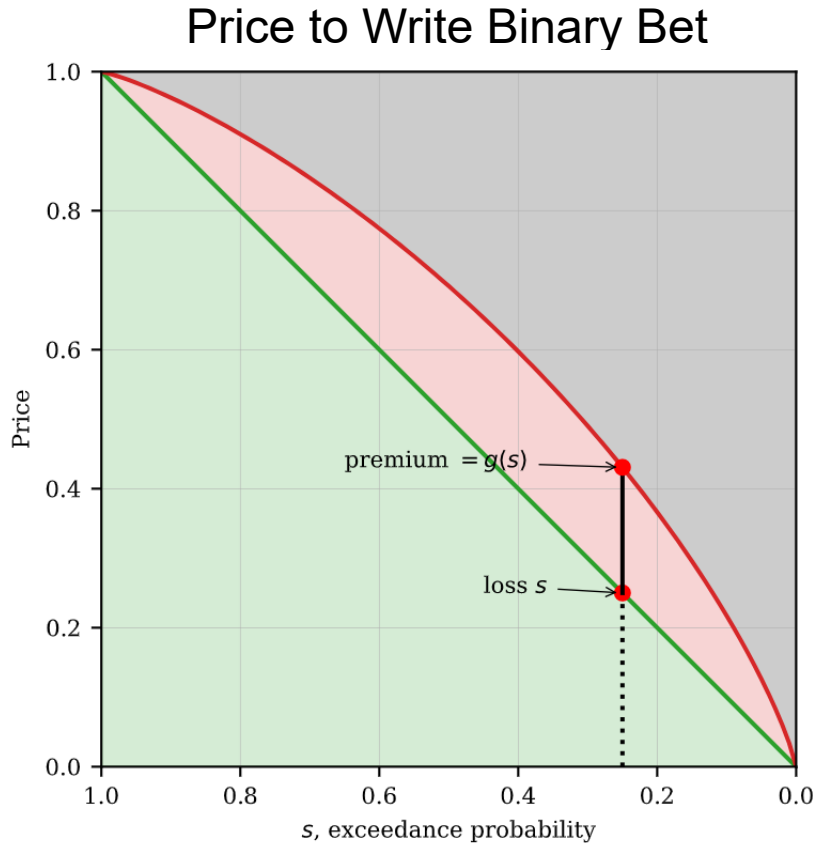

# Investor: ultimate risk bearer

- **Charge for risk**, e.g., because **ambiguity averse**, but not necessarily risk averse

- Market price of capital explained by a **distortion risk measure**  $\rho$ 
  - $\rho(X)$  gives market (ask) price of any loss payout distribution  $X$
  - DRMs are coherent, given by weighted average of TVaRs
  - Law invariant: price of risk only depends on probability of loss

# If price of risk only depends on probability of loss...

- **Distortion function**  $g(s)$  = price to assume risk of paying 1 with probability  $s$ , a **thin layer**

- $g(0) = 0$
- $g(1) = 1$
- $g$  increasing\*
- $g$  concave

- Higher loss = lower probability layers inherently more ambiguous

\* Note: x-axis reversed!  
Wang Transform, 0.5

# Thin layer insurance pricing statistics from distortion function

Price to Write Thin Layer

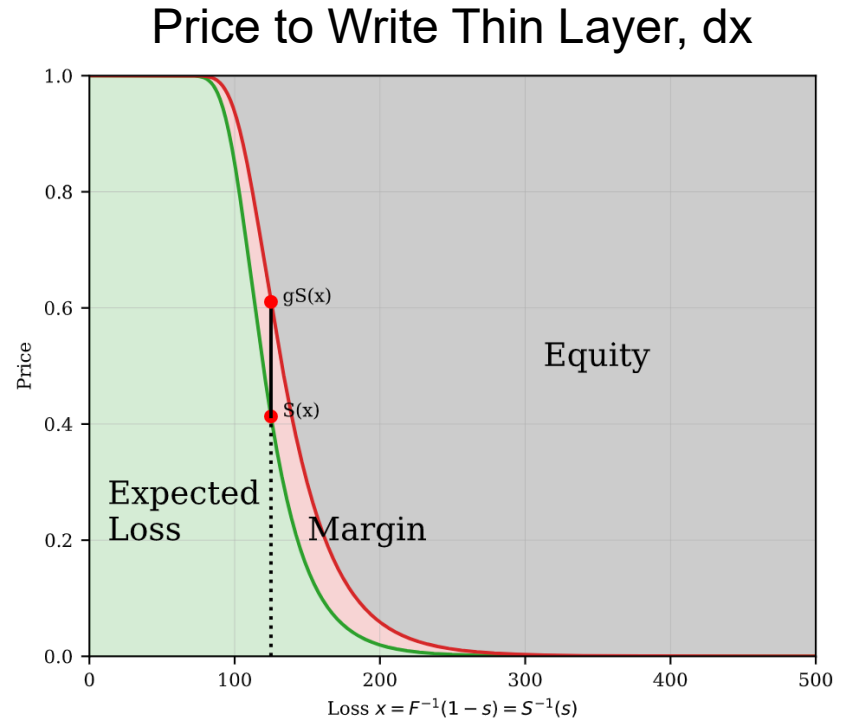

$$\text{Loss Ratio} = \frac{s}{g(s)}$$

$$\text{Premium to surplus leverage} = \frac{g(s)}{1-g(s)}$$

$$\text{ROE} = \frac{g(s)-s}{1-g(s)}$$

# Translate from probability of loss to dollars of loss

- Apply inverse distribution function, as per simulation
  
- Distortion thickens the tail
  - Increases expectation
  - Adds risk margin
  
- Acts on probabilities not on loss
  - Not a utility adjustment
  - Yarrri dual utility
  
- No objective **events**
  - Events defined implicitly by probability

## Limited liability expected loss & pricing implied by a distortion

Expected loss (LEV)  $E[X \wedge a] = \int_0^a S(x) dx = \int_0^a x f(x) dx + aS(a)$

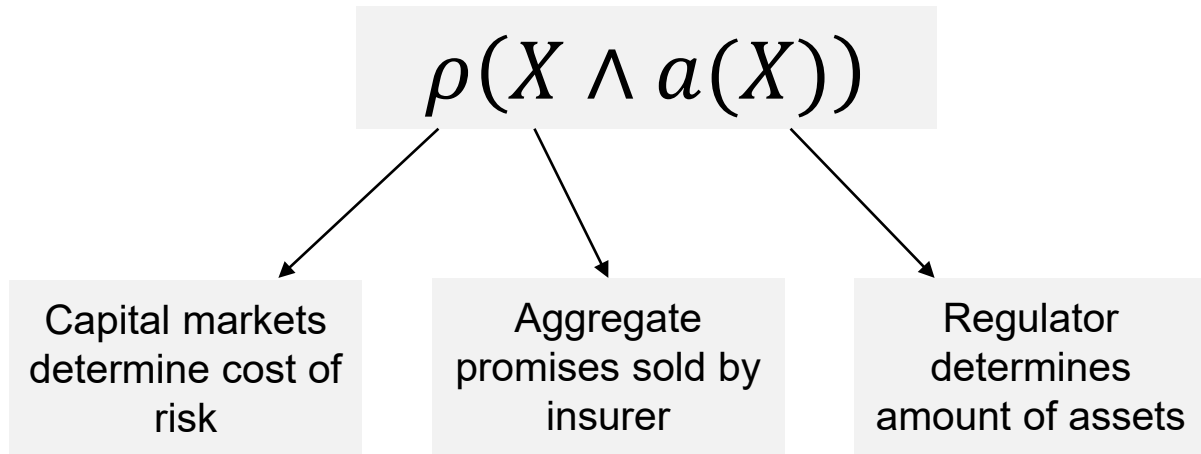

|
|  
 distorted probability      transformed pdf  
    state price density

Market premium  
Distorted expected loss

$$\rho(X \wedge a) = \int_0^a g(S(x)) dx = \int_0^a x g'(S(x)) f(x) dx + a g(S(a))$$

Average life expectancy: add up number of birthdays (survival) and divide by population

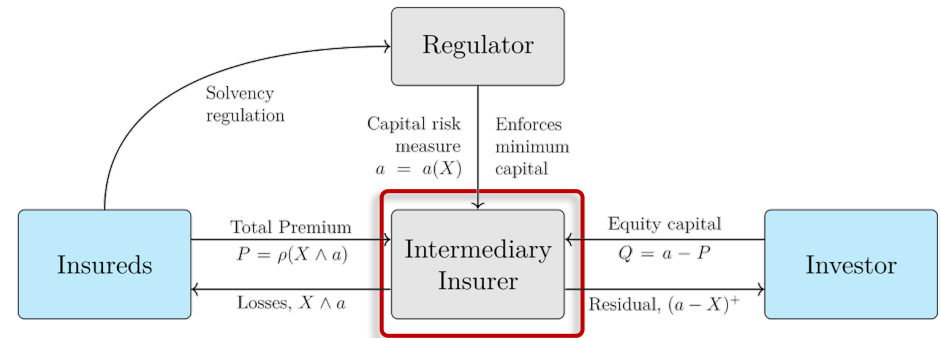

# Composite pricing functional

- If functionals  $\rho$  and  $a$  are monotonic, homogeneous, translation invariant, law invariant then so is composite
- Composite can **fail to be sub-additive** even when  $\rho$  and  $a$  are both sub-additive because diversification improves coverage quality for  $X_0 + X_1$  and hence it costs more

# Intermediary insurer

- **Limited liability entity with equal priority in default**

Incorporeal: insurer is a formula

- Operates like a cat bond to minimize **frictional costs** of holding capital
  - No transaction costs, no taxes
  - No management: no principle-agent problems
  - Minimal regulation, no trapped capital
  - Pure exposure to insurance risk, like a sidecars
- Key functions: unambiguous pricing/results and **enable limited liability**

## Loss payments: who gets what in default?

- Sold insurance promises

$$X = X_1 + \dots + X_n$$

- **Equal priority** payment to policy  $i$  with assets  $a$

$$\begin{aligned} X_i(a) &:= \begin{cases} X_i & X \leq a \\ a (X_i/X) & X > a \end{cases} \\ &= X_i \frac{X \wedge a}{X} \\ &= \frac{X_i}{X} X \wedge a \end{aligned}$$

- $X_i(a)$  sum to limited losses,  $X \wedge a$

- $\frac{X \wedge a}{X}$  = fixed payment pro rata factor applied to loss from each policy

- $\frac{X_i}{X}$  = variable share of available assets for policy  $i$  applied to...
- $X \wedge a$  amount of assets available to pay claims

## Archetype

- Two policy liabilities (debts)
  - $X_0$ : certain loss, 1000
  - $X_1$ : lognormal, mean 1000, cv 2.0
- Counterparty holds probabilistic reserves, to 90<sup>th</sup> percentile
  - 1000 for  $X_0$
  - 2272 for  $X_1$
- **Monoline**
  - $X_0$  no default haircut
  - $X_1$  has 27% default haircut
- **Pooled**
  - Assets 3272
  - $X_1$  has access to more assets in event of default, when it captures **more** than 70% (2272/3272) of assets
  - Lowers haircut to 24%
  - 3% transferred from  $X_0$  to  $X_1$
- **Conclusion**
  - Expected value of 970 for  $X_0$ , below promised actuarial value

## Expected loss and premium allocation by class and layer

$$\text{Expected Loss} = E[X_i(a)] = \int_0^a \underbrace{E\left[\frac{X_i}{X} \mid X > x\right]}_{\alpha_i(x)} S(x) dx = \int_0^a \alpha_i(x) S(x) dx$$

$$\text{Premium} = \rho(X_i(a)) = \int_0^a \underbrace{E^*\left[\frac{X_i}{X} \mid X > x\right]}_{\beta_i(x)} g(S(x)) dx = \int_0^a \beta_i(x) g(S(x)) dx$$

- $X_i/X$  = variable share of available assets for policy  $i$
- All quantities add-up
- No arbitrary choices
- Not marginal cost, not Aumann-Shapley value

### Assumptions

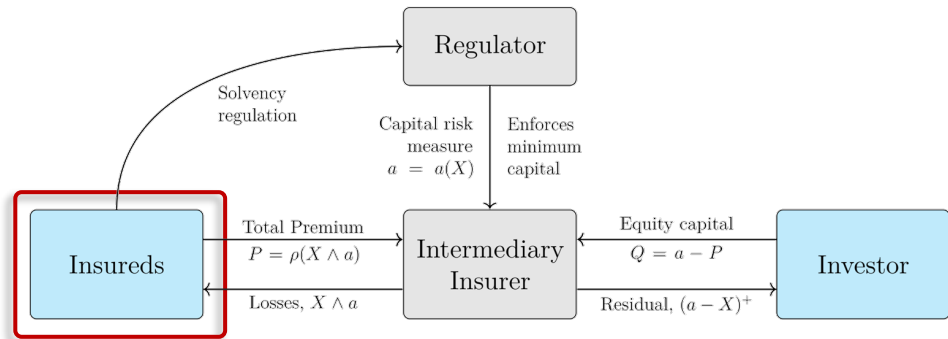

- Price with DRM  $g$
- Equal priority in default

Independence of  $X_i$  **not** required

Relies on comonotonic additivity of DRM

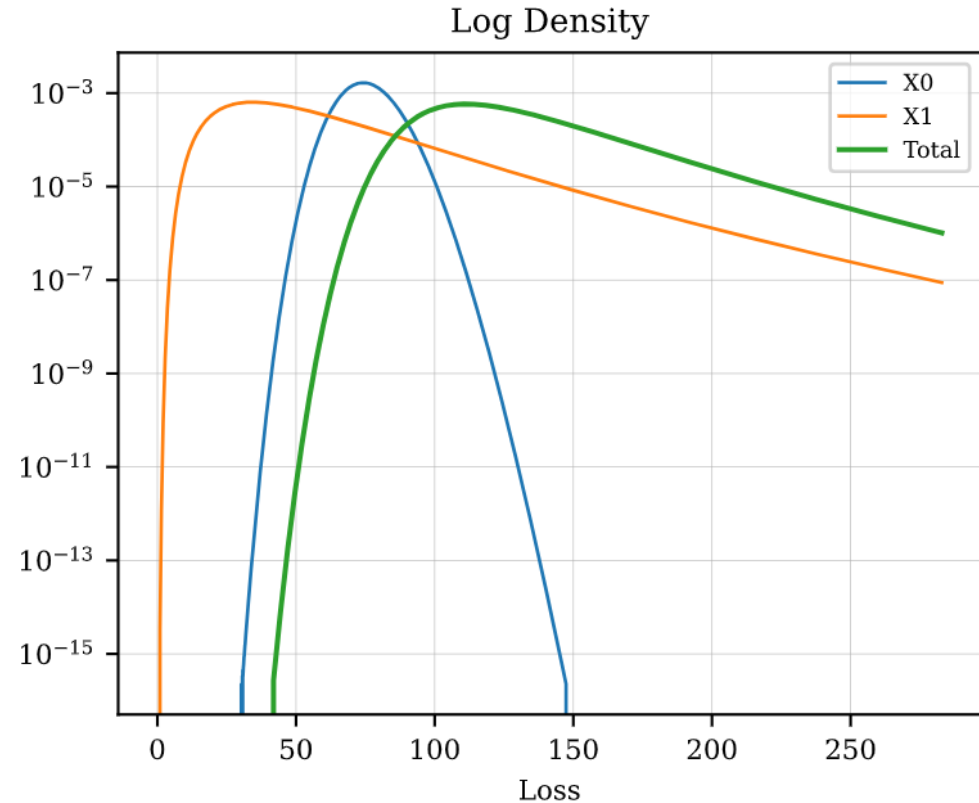

# Insured loss distributions

- **Two classes (lines) of insured**
  - $X_0$  thin-tailed class: high frequency, low severity; **Illinois personal auto**
  - $X_1$  thick-tailed class: catastrophe exposed; **Florida home**

- Risk is a characteristic of **class** and not the individual insured
- Homogeneous loss model: distribution scales, no shape change
  - Results for a sub-pool of a class are proportional to the results for whole class, i.e., model loss ratio, Myers Read and GBM models are homogenous
  - Mildenhall (Risks 2017)

# Example: Thin- and Thick-tailed two-class model

- Classes independent, convenience only
- $X_0$  thin class, EL 75, CV 10%, gamma distribution, comparable to personal auto
- $X_1$  thick class, EL 50, CV 53%, lognormal distribution, cat-exposed property
- Portfolio CV 22%
- Initially, expensive pricing, weak capital standard

## How will risks pool?

- Pools with the same class mix (e.g., monoline) can merge by homogeneity
- Pricing varies with mix: only one multiline pool (cheapest)
- There are only three possible market structures
  - Full pooling: one insurer
  - Two monoline insurers
  - One multiline pool insurer and one monoline insurer
- **Market defined by proportion  $t$  of risk class 1 in the pool,  $0 \leq t \leq 1$ , and**

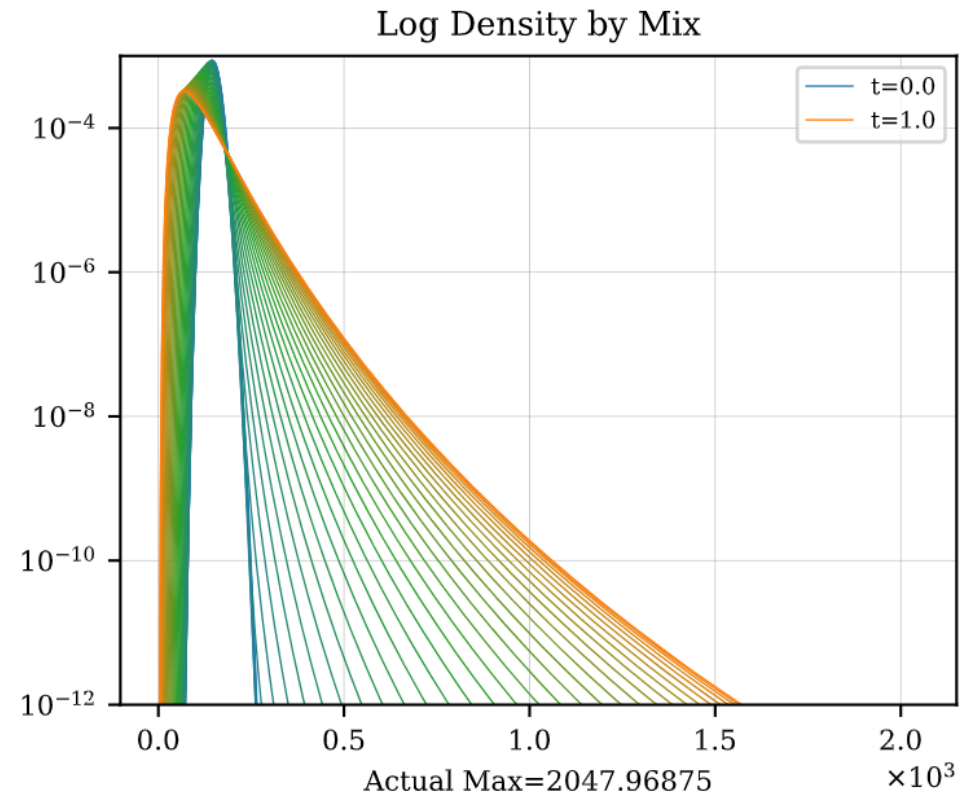

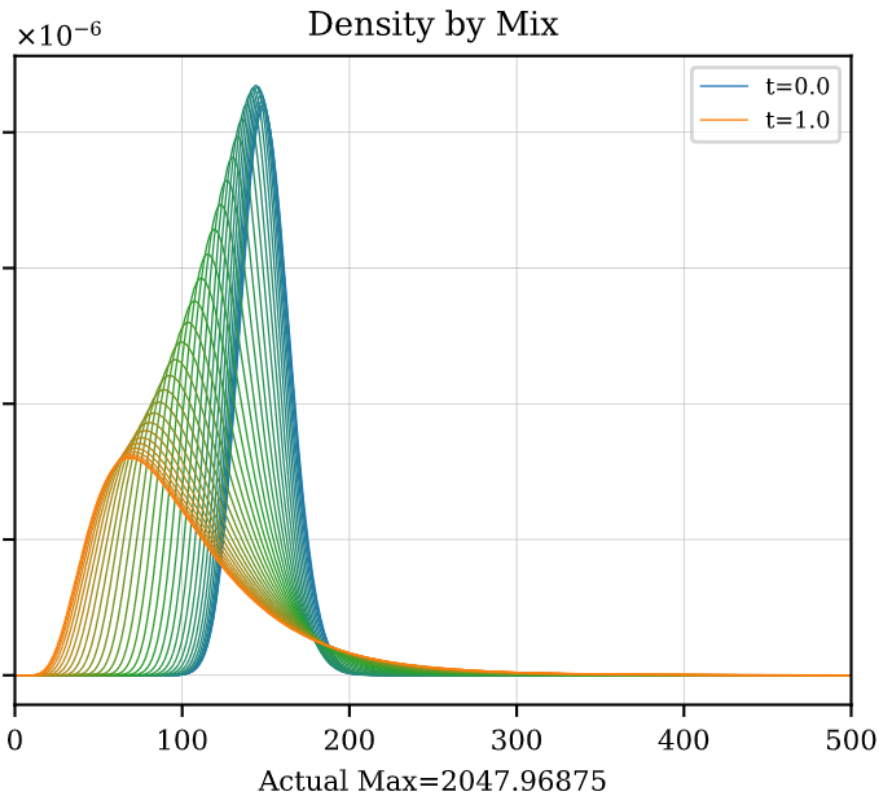

$t = 0, 1$       two monoline pools

$t = 0.5$       full pooling

$0 < t < 0.5$       class 0 fully pooled, class 1 split between pool and monoline

$0.5 < t < 1$       class 1 fully pooled, class 0 split between pool and monoline

# Total loss density, by portfolio mix $0 \leq t \leq 1$

- Pool outcome is  $X_t = (1 - t)X_0 + tX_1$
- Computations performed for 35 values of  $t$
- Graphs show how shape of aggregate portfolio transitions from  $X_0$  to  $X_1$

## Premium rates by class

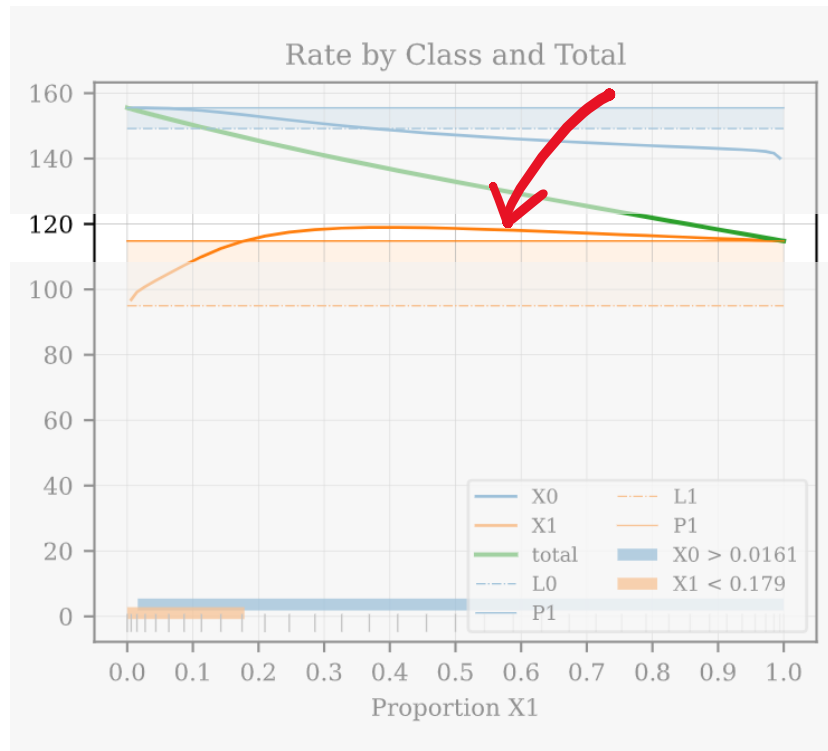

### Assumptions

- Wang hazard rho with 0.5 parameter
- Capital standard: 90% value at risk
- Premium rate = allocated premium / proportion of class, is comparable with monoline premium

- $t$ , the proportion of  $X_1$ , on x-axis
- Lines show **rate** for each class
  - **Blue  $X_0$  low, orange  $X_1$  high risk**
  - Green: blended pool rate
- Shaded bands at top show range from monoline loss cost and premium for each class
- Expected unlimited loss, before insurer default  $X_0 = 150$ ,  $X_1 = 100$ ; slightly less with limited capital
- Expensive pricing, weak capital standard

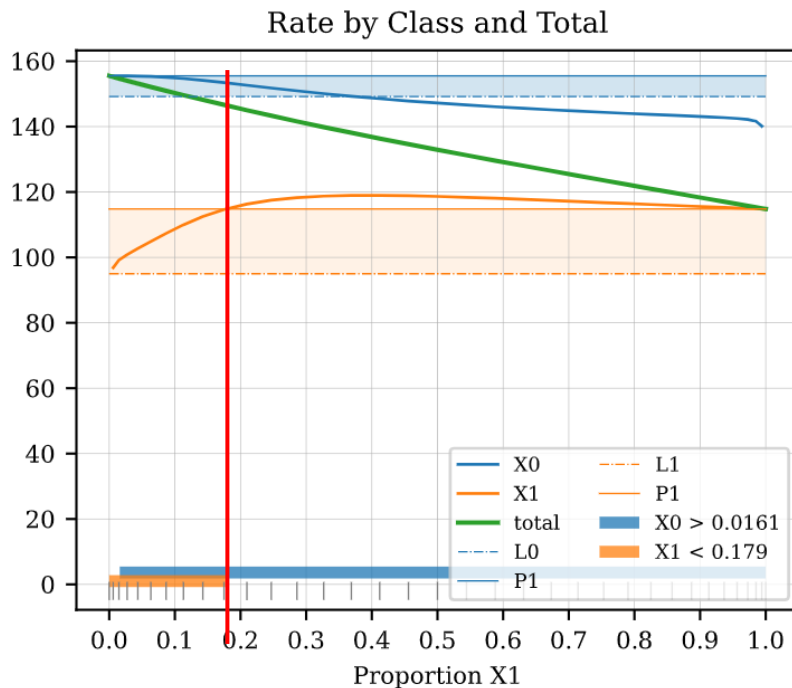

## Limited liability causes rate to bow up above monoline rate

- Pooling risky debt with certain debt benefits risky debt in default
- Benefit compensated through higher a priori premium
- Pool offers better coverage to riskier insureds = costs more
- Cost to provide insurance even when no benefit received, e.g., basis risk

# Partial pooling equilibrium solution

Hence Florida homeowners not fully pooled

- **Equilibrium solution,  $t = 0.179$** 
  - $X_0$  and 22% of  $X_1$  are pooled; remaining 78% of  $X_1$  written monoline
- **Why?**
  - $t > 0.179$ :  $X_1$  rate greater than monoline... $X_1$  will not pool
  - $t < 0.179$ :  $X_1$  insureds in pool get below monoline rate, with remainder monoline
  - Remainder will offer to pool with  $X_0$  at slightly higher rate until equilibrium reached at  $t = 0.179$
  - **$X_1$  pays monoline rate and  $X_0$  captures all diversification benefit**

# Sensitivity to cost of capital

Rate by Class and Total

Wang 0.25 parameter

Rate by Class and Total

Wang 1.5 parameter

## Stricter capital standard leads to full pooling outcome

- Feasible region overlap includes 50/50 pool
- $X_1$  premium  $\sim 128$  vs. 118 at  $p=0.9$

- 99.5% VaR capital standard (Solvency II level), base Wang 0.5 cost of capital
- **When  $t = 0.5$  is feasible for both lines, it is the equilibrium solution**
  - If  $t \neq 0.5$ , some insureds are forced into monoline rate
  - Monoline insureds offer to pool at more advantageous rate
  - $t \neq 0.5$  pool unravels
- At  $t = 0.5$ , all insureds pay lower multiline rate and no rational action can cause pool to unravel
- DemoTech in FL offers **weaker** standard

## Conclusions

- Pooling solution determined by subtle interaction between
  - Relative tail thickness of  $X_0$  and  $X_1$
  - Strength of capital standard
  - Cost of capital
  
- Full pooling is more likely with
  - Balanced tail thickness
  - Stronger capital standard
  
- Impact of cost of capital indeterminate
  
- Diversification benefit of pooling is eroded by economic transfers caused by limited liability, especially with weak capital standard

# Appendix

## Audit statistics and pricing summary

	X0	X1	total

- Example produced using aggregate Python package  
<https://github.com/mynl/aggregate>  
<https://aggregate.readthedocs.io/>
- pip install aggregate
- aggregate program for t=0.50 portfolio

```
port MIX_thin_thick
  agg X0 1 claim sev gamma 75.0 cv 0.1 fixed
  agg X1 1 claim sev lognorm 50.0 cv 0.5329 fixed
```

- Pricing results using 99.5% VaR and 90.0% capital and Wang 0.5 distortion for t=0.50 portfolio
- Market value liability = premium
- Note: by class rates shown in graphs are twice (divide by 0.5) the amounts shown here

## Expected loss and premium allocation by class and layer

$$\text{Expected Loss} = E[X_i(a)] = \int_0^a \underbrace{E\left[\frac{X_i}{X} \mid X > x\right]}_{\alpha_i(x)} S(x) dx = \int_0^a \alpha_i(x) S(x) dx$$

$$\text{Premium} = \rho(X_i(a)) = \int_0^a \underbrace{E^*\left[\frac{X_i}{X} \mid X > x\right]}_{\beta_i(x)} g(S(x)) dx = \int_0^a \beta_i(x) g(S(x)) dx$$

- $X_i/X$  = variable share of available assets for policy  $i$
- All quantities add-up
- No arbitrary choices
- Not marginal cost, not Aumann-Shapley value

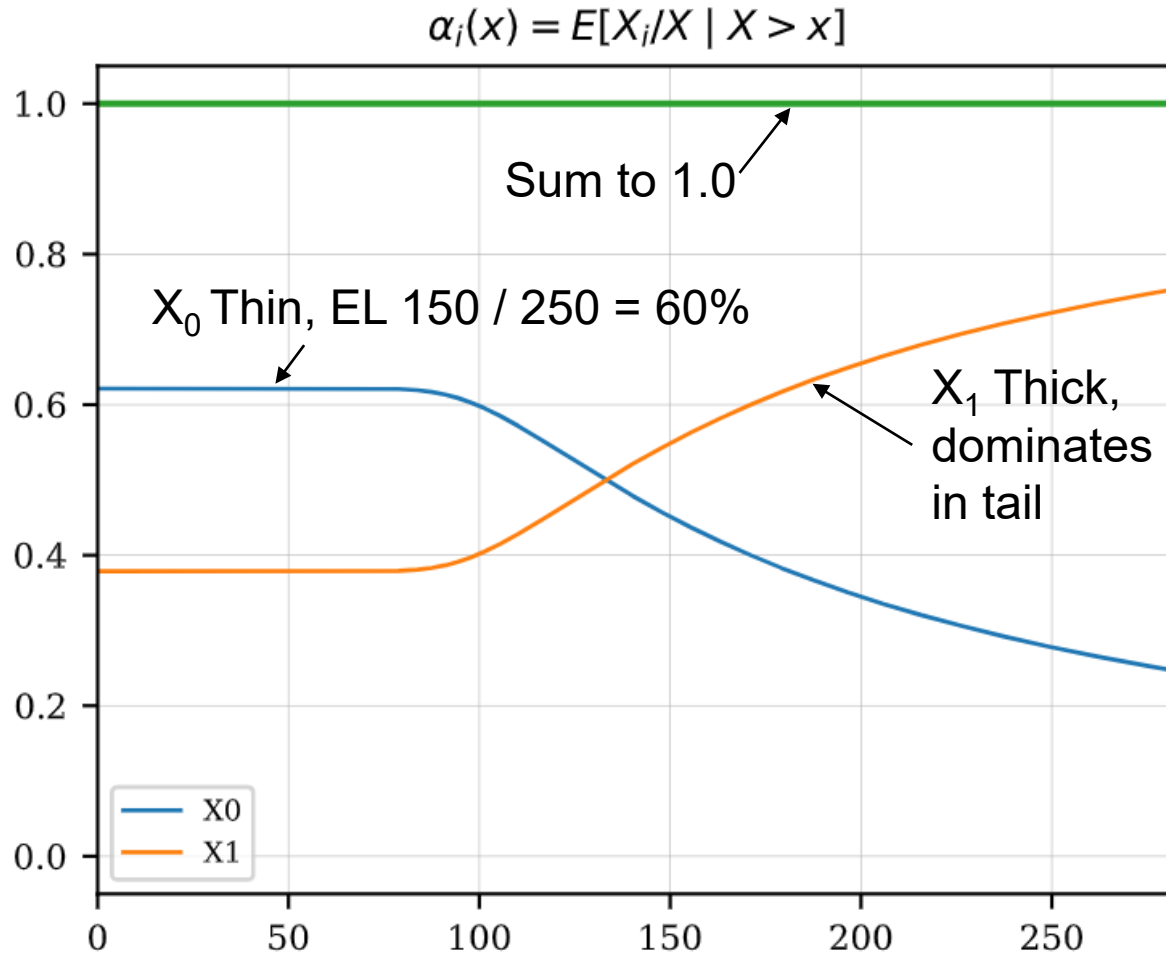

### Assumptions

- Price with DRM  $g$
- Equal priority in default

Independence of  $X_i$  **not** required

# alpha function: proportion of expected loss by layer

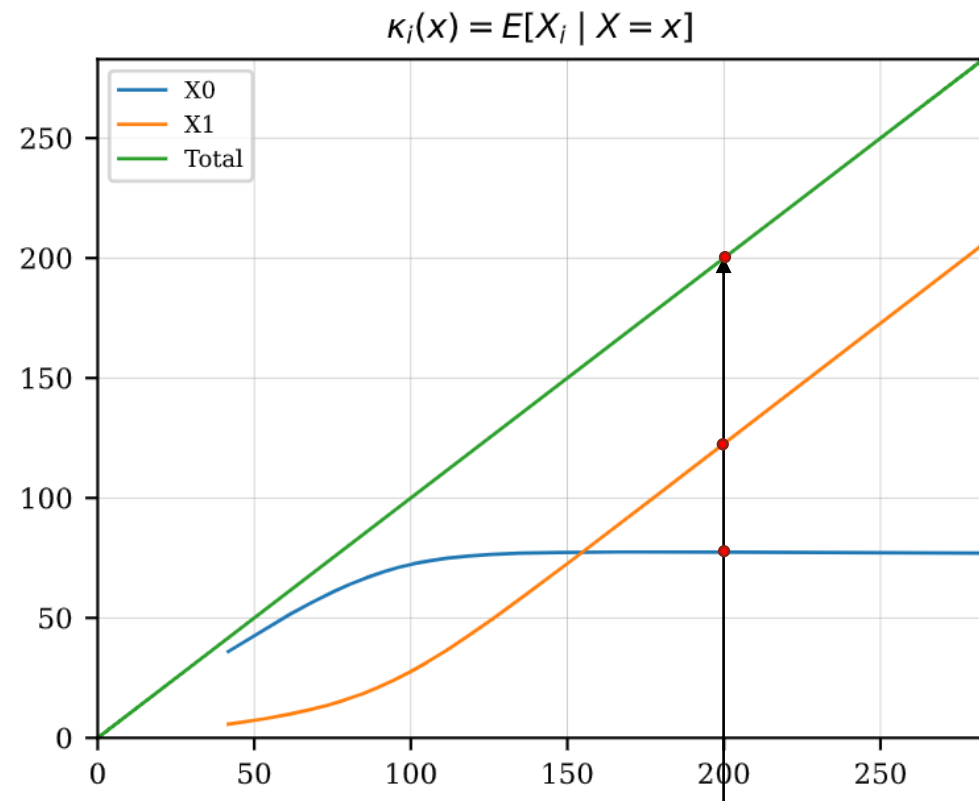

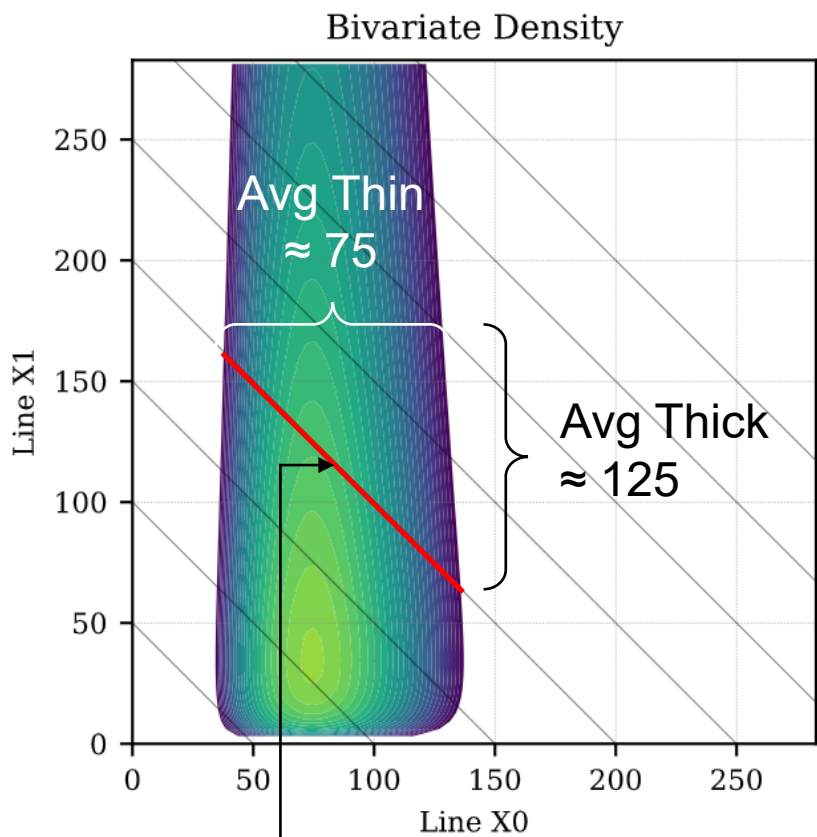

$$\alpha_i(x)S(x) = \int_x^\infty \frac{E[X_i | X = t]}{t} f_X(t) dt$$

# $E[X_i | X=x]$ : building block function for alpha and beta

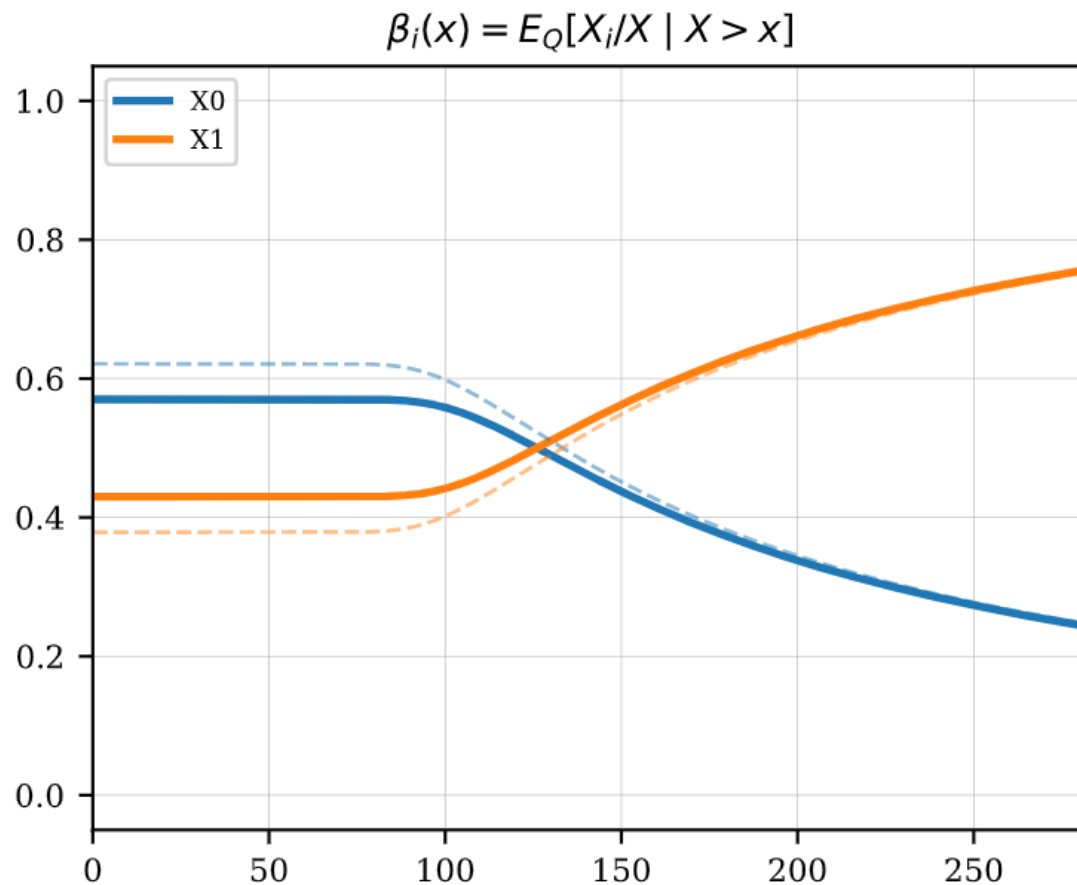

Condition on  $X = 200$

## beta function: proportion of premium by layer

- $\beta_i(x)$ , solid line, is a risk adjusted version of  $\alpha_i(x)$ , dashed, putting more weight on right tail

When  $\alpha_i(x)$  **increases**  $\beta_i(x)$  is **above**  $\alpha_i(x)$ , positive margins = **Thick orange** (solid above dashed)

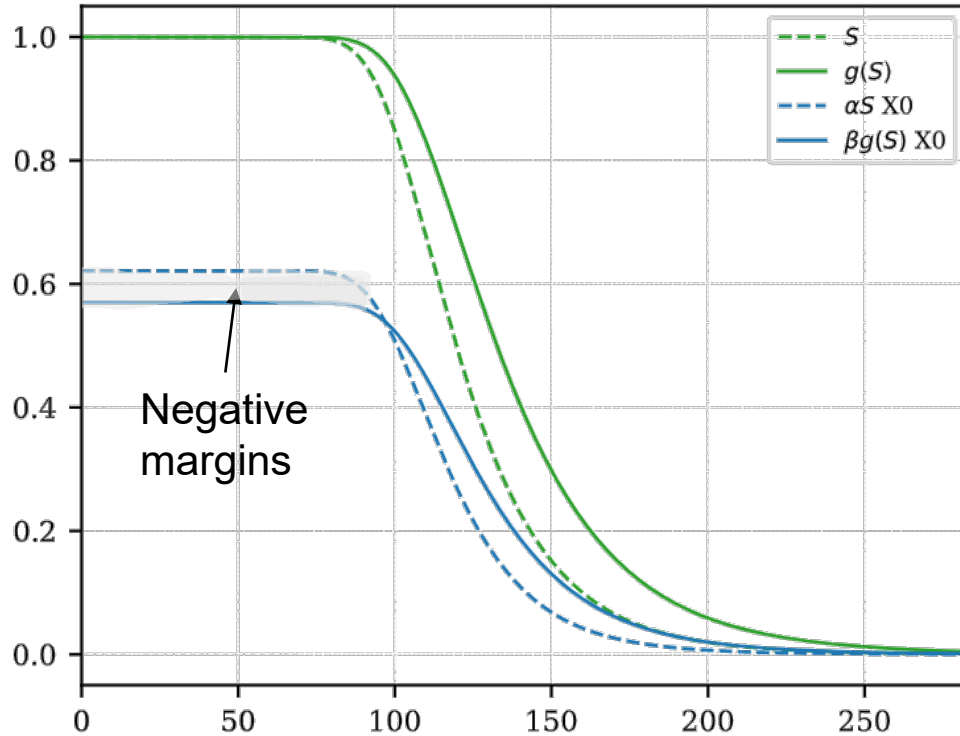

When  $\alpha_i(x)$  **decreases**  $\beta_i(x)$  is **below**  $\alpha_i(x)$ , negative margins for some layers = **Thin blue**

$$\text{Margin} = \beta_i(x)g(S(x)) - \alpha_i(x)S(x)$$

# Margins by asset layer, by class

Line = X0

Line = X1

- Thin... $\alpha_i(x)$  **decreases**... $\beta_i(x)$  **below**  $\alpha_i(x)$
- $\beta_i(x)g(S(x))$  may be **below**  $\alpha_i(x)S(x)$
- Possible negative margins for low layers
- Eventual cumulative margin positive

- Thick... $\alpha_i(x)$  **increases**... $\beta_i(x)$  **above**  $\alpha_i(x)$
- $\beta_i(x)g(S(x))$  **above**  $\alpha_i(x)S(x)$  since  $g(S)>S$
- Positive margins at all layers of capital
